

Where Electoral Votes Are, and Where They Are Contested

Fifty-one rows, two inequalities, and the difference between where the votes are and where they matter

84-355 Democracy's Data

August 2026

Americans do not elect a president. They elect fifty-one separate slates of electors, under fifty-one separate rules, and the electors elect a president. The entire 2024 result, as the law understands it, therefore fits in fifty-one rows. Here is one of them.

State	Abbrev	Electoral votes	Harris %	Trump %	Other %	Winner	Margin
Pennsylvania	PA	19	48.66	50.37	0	Trump	1.71

Two things about that row decide everything that follows.

harris and trump are percentages, not counts. Pennsylvania's 1.71-point margin and Wyoming's 45.76-point margin are the same *kind* of number and nothing like the same event. A percentage has no size in it.

ev is not a measurement at all. It is a legal quantity, fixed by the 2020 census and unchanged by anything that happened on election day. It is the only column in the file that is not about voters, and it is the column that decides the election.

Every electoral system is a machine for turning a distribution of preferences into a single decision, and every such machine throws information away. The question is never whether it distorts, because it always does. The question is **which distortions it produces, whom they favor, and whether anyone chose them.** The Electoral College's distortions were not designed for the country now living under them. They are the residue of an eighteenth-century compromise about slavery, federalism and the mechanics of a count, and they are the reason a presidential campaign can rationally ignore most of the population.

Nearly everyone agrees the system is unequal. The live argument is about **which inequality is the important one.** One candidate is the small-state bonus: every state gets two electors for its senators regardless of population, so Wyoming's 3 electors cover far fewer people than California's 54. The other is winner-take-all: forty-eight states award every elector to the plurality winner, erasing the losing side of every state. These are different problems with different remedies, and a reform that fixes one can leave the other entirely untouched.

01 Measured, legislated, drawn

That one row is three different kinds of thing sitting in a single line, and telling them apart is most of what this chapter needs.

The vote percentages were measured. They come from Jason Timm's `PresElectionResults` compilation, which rests on the certified state canvasses. That is the same private chain of custody that carries American election returns generally, because certification is an act each state performs for itself and no federal body adds up the results. Somebody counted ballots in a county, a state canvassing board certified a total, and a compiler on GitHub assembled fifty-one of those certifications into one table.

Getting that table costs about a second: one `.rda` file at a public URL, no key, no form, nothing to piece together. But a second is what *this* chapter paid, not what the column cost. Fifty-one canvasses had to be located, read, and forced into columns that would sit beside each other, by somebody who chose to, and then kept current across elections. That is the bargain a compilation offers, and it is the ordinary way election data reaches anyone. It arrives usable because the cleaning already happened, somewhere else, before the download.

Two things follow that a reader should carry. The judgment calls are already made, and listed nowhere in the file: a percentage does not record which of the fifty-one canvasses was awkward. And the file continues to exist for exactly as long as one person keeps choosing to build it.

The electoral votes were legislated, and they did not come from that source at all. The `ev` column is typed in by hand, as a list of 51 numbers reflecting the 2020 apportionment. One line checks it, asserting that the values add to 538 and that there are 51 of them. That is worth sitting with. The column that decides the presidency is typed in by hand and checked by one sum. It is nonetheless the most certain number in the file, because it is a legal fact rather than an estimate of anything.

The tile coordinates were drawn. `col` and `row` are neither measurement nor law; they are a design decision, also typed into the build, and they exist so that the maps below can show electoral weight without showing land. A reader who disagreed with the layout could change two columns and every map in this chapter would move.

This resolution is the right one, not a simplification of something better. The rule under examination operates on whole states, so a 51-row table is the object the law actually acts on. What is genuinely lost is that these are percentages rather than counts, so turnout and population are absent and cannot be recovered. And comparing the rows assumes something the law never claims. Fifty-one jurisdictions each decided for themselves what counts as a vote, which ballots could be fixed, and when counting stopped. The certified percentages arrive looking perfectly comparable anyway.

There is also a rule the table has no room for. One row per state with one winner per state cannot express a state that splits its electors by congressional district, which two states do. A schema is a claim about how the world is arranged, and this one quietly claims that winner-take-all is universal.

The cleaning was almost nothing, and the almost is the interesting part. The build subsets the compilation to 2024, attaches the two typed vectors, and writes the file. It verifies the electoral votes and it does not verify the vote percentages — which is exactly where the next section begins.

02 One row, assembled from three places

Watch a row get built. Two of the three ingredients are shown here exactly as they arrive.

The percentages come out of the downloaded `.rda`, which for 2024 holds 51 rows in seven columns. Alabama and California, verbatim:

	year	state_abbrev	winner	party_win	democrat	other	republican
	2024	AL	Donald Trump	republican	34.10	NA	64.57
	2024	CA	Kamala Harris	democrat	58.47	NA	38.33

The electoral votes come from nowhere at all. They are typed in by hand, and this is the whole of where that column came from:

```
ev <- c(AL=9, AK=3, AZ=11, AR=6, CA=54, CO=10, CT=7, DE=3, DC=3,
      FL=30, GA=16, HI=4, ID=4, IL=19, IN=11, IA=6, KS=6, KY=8,
      ... 33 more ...
stopifnot(sum(ev) == 538, length(ev) == 51)
```

And the tile coordinates are typed in the same way, as a small block of text that is a picture of the country rather than a measurement of it:

abbrev	col	row
AL	7	7
CA	1	5

Put them together and you get this:

State	Abbrev	Ev	Harris	Trump	Other	Winner	Col	Row	Margin
Alabama	AL	9	34.10	64.57	0	Trump	7	7	30.47
California	CA	54	58.47	38.33	0	Harris	1	5	-20.14

Nothing in that row records where any of it came from. `harris` was counted by election officials in sixty-seven Alabama counties and certified by a canvassing board. `ev` is a number in a statute. `col` is somebody's opinion about where Alabama looks right on a grid. They are the same width, the same type, and they sit in the same row, and a reader has no way to tell them apart without leaving the file.

The scanner makes part of that visible and misses the rest:

Field	Stored	Level	Distinct	Missing	Mismatch
ev	integer	count	20	0	
other	numeric	continuous	9	0	

Field	Stored	Level	Distinct	Missing	Mismatch
col	integer	categorical	11	0	stored as a number; the values are labels, not amounts
row	integer	categorical	8	0	stored as a number; the values are labels, not amounts

It catches `col` and `row`: whole numbers that are labels, not amounts, so averaging them would be meaningless. It cannot catch `ev`, which is a perfectly ordinary count and is also a hand-keyed constant. **No automatic check can tell you that a column was typed rather than measured.**

Where the row was decided rather than assembled

A missing value became a zero, and this is the one that matters. Look at the `other` column in the raw rows above: NA for both states, and for 42 of the 51 altogether. The compilation records a third-party figure only sporadically. The build turns every one of those into 0 — and the scan above duly reports that `other` has no missing values, because by the time anything looks, it hasn't. **The file's own final check, `stopifnot(!any(is.na(out)))`, passes for the same reason.** An assertion that the data has no holes, satisfied by having filled them.

That single substitution is why the next section exists, and why Figure 1 has to be drawn: a zero in `other` does not mean nobody voted third-party in Alabama. It means nobody wrote the number down.

The winner column has no room for the truth. `party_win` collapses to Harris or Trump, one label per state. Two states award electors by congressional district and can therefore split, and there is no cell in this schema in which that could be expressed. The table does not get it wrong so much as it cannot say it.

The verification checks the column that could not be wrong. `ev` is asserted to sum to 538 across 51 entries — a real check, and it would catch a typo. The percentages get no equivalent, and they are the ones that came from somewhere else, through four sets of hands, with nobody's judgment calls written down.

03 Fifty-one rows, and one column that lies

Quantity	Value
Rows	51
Electoral votes in total	538
Jurisdictions Harris carried	20
States reporting a nonzero third-party vote	9
States whose three percentages sum to 100	0

Fifty-one rows: fifty states and the District of Columbia, which has had three electoral votes since the Twenty-Third Amendment and no voting representation in Congress.

Then the last two rows of that table. **other is zero in 42 of 51 states, and not one state's three percentages add to 100.** Every state is short by between 0.5 and 3.8 points.

Figure 1 shows that shortfall for every jurisdiction, split by whether the file reported a third-party number at all.

Figure 1. Every jurisdiction falls short of 100%. The horizontal position is the shortfall: 100 minus the three reported percentages. Hollow circles are the 9 jurisdictions that report a third-party number and are short by 1.34 points on average; filled circles are the 42 that report a zero, and they are short by 2.06. The vertical bars are those two means.

The shortfall is the third-party vote, sitting there unlabeled. A zero in this column does not mean nobody voted third party. It means whoever assembled the file did not tabulate it separately. The 42 states reporting a zero are short by 2.06 points on average, against 1.34 for the 9 that report something. That is exactly what you would expect if the zero were a missing value carrying the whole third-party vote inside it. **A zero and a missing value are not the same thing, and a spreadsheet cannot tell them apart.**

This is the first live example in this chapter of not knowing where a number came from. It is a reason to find out where a set of returns came from before arguing about what they say.

04 The first map anybody makes

Color each state by margin, meaning Trump's percentage minus Harris's, and draw every state the same size, laid out roughly where it belongs. Land does not vote, so we will not draw land.

Then draw it a second time with each square's **area** proportional to that state's electoral votes. Neither version is the map; both are choices, and the pair of them is the point. Figure 2 is both.

One square per jurisdiction, all the same size

The same squares, area proportional to electoral votes

Figure 2. The 2024 result as a grid, drawn twice. One square per jurisdiction, positioned roughly where the state belongs and colored by margin, on a scale capped at 30 points in each direction. The margin is Trump's percentage minus Harris's. In the first version every square is the same size, so every state counts once. In the second, each square's area is proportional to its electoral votes, which is what the Constitution actually counts.

Land does not vote and no land is drawn. 10 of the 51 jurisdictions lie beyond the cap and are painted the same extreme shade; the largest is District of Columbia at -83.8.

The margin runs from **-83.8 in District of Columbia to 45.8 in Wyoming** – a spread of 130 points. It is a picture of a country pulled to its two ends.

Read the legend before you read the map. The color scale is **capped at 30 points in each direction**. So the 10 jurisdictions beyond that cap are all painted the same extreme shade, even though they are nothing like each other. District of Columbia at -83.8 is 1.8 times as lopsided as Wyoming at 45.8, and the map cannot show you that. A cap makes the middle of the scale readable by making the ends of it lie. **Every choropleth you will ever see has made this trade; most do not tell you.**

05 The same data, colored differently

Now color by Harris's *share* instead of the margin. Nothing about the data changes, and to keep the comparison honest nothing about the drawing changes either: same 51 squares, same positions, same blue-white-red ramp, same cap of 30 points either side of a tie. The left map measures the gap between the two candidates. The right map measures how far Harris's own share sits from 50.

Figure 3. Margin and share, side by side, on one color ramp. The same 51 squares in the same positions, the same blue-white-red scale, the same cap of 30 points either side of a tie. On the left, color is the gap between the two candidates; on the right, it is how far Harris's own share sits from 50. 10 jurisdictions reach the cap on the left and 1 on the right. Nothing about the country differs between the two panels.

The right-hand map is the paler one, and the reason is arithmetic rather than politics. A margin counts the same voters twice, once as a gain for one candidate and once as a loss for the other. So it is about 2.0 times a share's distance from 50. On the margin map 10

jurisdictions are dark enough to hit the cap; on the share map, only 1 is. Nothing about the country changed between those two pictures.

Scale	Lowest	Highest	Spread
Margin (Trump % minus Harris %)	-83.8 (District of Columbia)	+45.8 (Wyoming)	130
Harris share of the vote (%)	25.8 (Wyoming)	90.3 (District of Columbia)	64

Halving the spread halves the visual drama. A margin scale spans 130 points; a share scale spans 64. On the share map the blowout states stop screaming and the country looks divided but overlapping.

The maps make the difference visible. Figure 4 makes it countable. Both rows hold the same 51 jurisdictions, measured in percentage points and anchored at the same place, a tie. The gray line joining each jurisdiction's two positions is the whole argument: every one of them sits about twice as far from the tie on the margin row as on the share row.

Figure 4. The same 51 jurisdictions, measured two ways from a tie. Circles are margins, triangles are Harris's distance from 50, and each gray line joins one jurisdiction's two positions. The margin scale spans 130 points and the share scale 64, a factor of 2.0, because both ends of the share scale move in toward the tie at once.

Neither map is lying. A 70-30 state and a 60-40 state sit 20 points apart on a margin scale and 10 apart on a share scale. The same two electorates, with one gap drawn twice as wide as the other. **The choice of scale is an argument**, and the only dishonest version is the one that does not tell you which was chosen.

06 Counting to 270

The map shows who won where. It does not show who won.

Candidate	Electoral votes
Harris	226
Trump	312

312 to 226, and 538 in total. That is the certified result.

But look at what the arithmetic just assumed. It handed **every** one of a state's electoral votes to whoever carried it, which is winner-take-all. **Maine and Nebraska do not do that.** Both award two electors statewide and one per congressional district, and in 2024 both split: Trump carried Maine's second district, Harris carried Nebraska's second.

State	Statewide winner	Electoral votes	Margin
Maine	Harris	4	-6.94
Nebraska	Trump	5	20.46

Winner-take-all gives Harris all 4 of Maine's and none of Nebraska's. Reality gave her three from Maine and one from Nebraska. Four either way. **The two errors canceled.**

That is luck, not a rule. A model that produces the right number for the wrong reason will keep producing it until the day it does not, and nothing in the output announces which day that is.

07 Where the electoral votes are

Sort the states by electoral votes and add them up until you cross 270.

State	Electoral votes	Running total	Margin
California	54	54	-20.1
Texas	40	94	13.7
Florida	30	124	13.1
New York	28	152	-12.4
Illinois	19	171	-10.9
Pennsylvania	19	190	1.7
Ohio	17	207	11.3
Georgia	16	223	2.2
North Carolina	16	239	3.2
Michigan	15	254	1.4
New Jersey	14	268	-5.9

State	Electoral votes	Running total	Margin
Virginia	13	281	-5.8

12 states of 51 hold a majority of the Electoral College. The ten largest alone hold NA, which is NA% of the whole.

That number is genuinely striking, and it is where most accounts of the Electoral College stop: a handful of big states hold the presidency, so a campaign should go where the electoral votes are.

There is a column in that table which has not been used yet.

08 Large is not the same as close

The margin column changes the picture completely.

Group	Value
The 12 states that reach 270	12
... of those, decided by under 5 points	4
All states decided by under 5 points	8
Their share of the Electoral College	17.8%

Only 4 of the 12 states that reach 270 were decided by less than five points. California, Texas, New York, Illinois and Ohio are enormous and were never in doubt; each was decided by double digits. They contribute electoral votes to a total, not decisions to a contest.

The states that decide an election are the ones that are **large and close**, and that is a much smaller set:

State	Electoral votes	Harris %	Trump %	Margin
Pennsylvania	19	48.66	50.37	1.71
Georgia	16	48.53	50.73	2.20
North Carolina	16	47.65	50.86	3.21
Michigan	15	48.31	49.73	1.42
Minnesota	10	50.92	46.68	-4.24
Wisconsin	10	48.74	49.60	0.86
Nevada	6	47.49	50.59	3.10
New Hampshire	4	50.65	47.87	-2.78

8 states holding 96 electoral votes carried the entire uncertainty of the election. That is **17.8% of the College**. Tighten the threshold to three points and it is 5 states and 64 electoral votes. Figure 5 puts every jurisdiction on the two axes at once.

Figure 5. Size against closeness, one point per jurisdiction. The vertical axis is electoral votes and the horizontal axis is the margin, ignoring its sign; the shaded band holds the 8 jurisdictions decided by under five points. The states that decide an election sit in the upper left, large and close. The upper right is where most of the Electoral College lives: enormous, and settled before the campaign began.

“Where the votes are” and “where the votes are in play” are different questions with almost disjoint answers, and the whole logic of campaign strategy lives in the gap between them. A campaign that allocated its time in proportion to electoral votes would be behaving irrationally, and every campaign knows it.

09 What the rule does to a voter

Put the two inequalities side by side and give each a number.

Inequality	What it does	Who it helps	Fixed by
Small-state bonus	Every state gets 2 electors for its senators regardless of size (WY 3 vs CA 54 electoral votes)	Voters in small states, of either party	Nothing short of a constitutional amendment
Winner-take-all	A plurality takes the whole state, so the losing side of every state is erased	Voters in close states, of either party	State law — a state could change it tomorrow

These are separable. That matters, because reforms are usually proposed as though they were the same problem.

10 Abolish winner-take-all and see what happens

Split each state's electors in proportion to its two-party vote instead of awarding them all to the winner.

Before you read the table, commit to a winner and to a margin. Under winner-take-all the result was 312–226, a margin of 86 electoral votes. Now give every state's electors out in proportion to its two-party vote instead. **Does the winner change – and what is the new margin?**

Write down a name and a number. They are two separate questions, and the answer to one of them is much larger than most people expect while the answer to the other is not what the size of that change would suggest.

Rule	Harris	Trump	Margin
Winner-take-all (actual)	226	312	86
Proportional within each state	264	274	10

The margin collapses from 86 electoral votes to 10. Trump still wins.

The collapse is not spread evenly. Figure 6 shows what the rule change does state by state.

the 51 jurisdictions, ordered by the size of the change

Figure 6. Electoral votes moved by replacing winner-take-all with proportional allocation. One bar per jurisdiction, ordered by the size of the change; blue bars move electors to Harris, red bars to Trump. The reform hands her 132 electors out of states she lost and

takes 94 out of states she carried, and 20 of the 51 jurisdictions move by two electoral votes or fewer.

How far a state moves is almost entirely a matter of how large it is, and hardly at all a matter of how close it was. The size of the move correlates 0.99 with a state's electoral votes.

This is the most useful result in the file, and not because of the winner. Proportional allocation is fairer to **voters in landslide states** — a Republican in California and a Democrat in Wyoming would finally count for something. It is emphatically not fairer to **small states**, which keep their two-senator bonus under either rule. The reform changes *which* inequity you live with; it does not remove inequity, and it does not touch the malapportionment at the heart of the system.

One more thing worth noticing: the proportional columns sum to 538, exactly 538. **They did not have to.** Each state was rounded independently, and independent rounding does not have to reconcile to a fixed total. That is the apportionment problem, which is a chapter of its own.

11 Where the election was actually decided

The 2024 electoral map was decided by 8 states holding 17.8% of the Electoral College, and the 12 states large enough between them to reach 270 are mostly not those states. Size and closeness are nearly independent properties, and only one of them determines where a campaign goes.

Sharper than that: the Electoral College's two inequalities are independent of each other, and the reform most often proposed, proportional allocation, addresses only one of them. On 2024's numbers it would have changed the margin by 76 electoral votes and not the outcome.

What these rows cannot say is how much of that concentration is produced by the rule and how much by the country. Close states would be more interesting than safe ones under almost any system; winner-take-all sharpens the difference, and nothing here separates the sharpening from the underlying distribution. Nor can they say anything about turnout, population, or votes per elector, because every number in the file is either a percentage or a legal quantity. **There are no people in this file.**

12 Does the Electoral College help small states?

This is the standard defense, and the evidence against it is stronger than most people realize. Edwards (2004) assembles it at length: the College does not reliably protect small states, racial minorities, or federalism, because the two-senator bonus is swamped by winner-take-all. A small *safe* state receives essentially no campaign attention despite its inflated per-voter weight: Wyoming, Vermont, the Dakotas. The states that get attention are the ones in the upper-left corner of Figure 5, and most of them are large.

There is a formal version of the same dispute. A tradition of voting-power indexes, running back to Banzhaf, argued that winner-take-all makes voters in *large* states more powerful, because a large state delivers a bigger block. Those indexes rest on an assumption: that every possible arrangement of votes is equally likely. Gelman, Katz and Bafumi (2004) tested it against actual election data and rejected it. **The probability of casting a**

decisive vote turns out to scale roughly as $1/n$ rather than $1/\sqrt{n}$, which means the standard indexes systematically overstate the power of voters in large jurisdictions.

The honest summary is that the direction of the large-state/small-state bias is still contested among people who work on it carefully, and that both sides agree the biggest effect is neither: it is **closeness**.

13 Is a state's competitiveness a property of the state?

No, and this is where the map misleads most. Competitiveness is a property of a state *in a given election*. The Solid South was uncompetitive for eighty years and then was not; Vermont ran the same path in reverse. The 8 competitive states of 2024 are not a permanent list, and an account that treated them as one would be making exactly the mistake this chapter exists to prevent.

14 What fifty-one rows can testify to

The strengths of this file are unusual ones. It is complete: all 51 jurisdictions, no missing rows, and nothing imputed — no gap filled in by guessing. The electoral vote counts are legal facts rather than estimates, so the arithmetic of 270 and of proportional allocation depends on no measurement at all. And it is small enough that every claim made above can be checked by eye against the tables that produced it.

The weaknesses are the price of that smallness. The vote columns are percentages, not counts. So there is no turnout, no population and no votes per elector, and the per-voter inequality that the whole small-state argument turns on cannot be computed here at all. The ~~other~~ column is unusable. 42 of 51 jurisdictions report a zero that is not a zero, and no jurisdiction's percentages add to 100.

Winner-take-all is assumed throughout, so Maine and Nebraska are misrepresented. In 2024 the two errors happened to cancel, which is luck rather than correctness. It is one election, so nothing here is a trend, and the list of competitive states is a snapshot of a single November.

And everything is state-level, which hides the rule's most important feature: a state's losing voters vanish. The file has no unit smaller than a state, so the disappearance is invisible in it.

Three questions stay open, and none of them will be settled by adding rows. Whether winner-take-all favors large states or small ones on net is still disputed, and the dispute is about a model rather than about these numbers. What proportional allocation would actually do is not what it does to a fixed set of votes. Change the rule and you change the campaign, the turnout and probably the vote itself. The arithmetic above holds all of that constant, which is precisely what a real reform would not. And whether the concentration in Figure 5 is stable is a question one election cannot answer.

What can be said is this. A country appointing 538 electors settled the question inside 8 states holding 96 of them. The rule producing that concentration is written in state law rather than in the Constitution, and could be changed by any legislature that wanted to. And the change would leave the older inequality exactly where the Convention put it: two electors per state, whoever lives there.

15 Sources

Data

- State-level 2024 presidential returns, from Jason Timm's `PresElectionResults` compilation (<https://github.com/jaytimm/PresElectionResults>), which rests on the certified state canvasses. Electoral vote counts reflect the 2020 census apportionment.

The data itself

Every figure above is drawn from these tables. They are plain CSV, they open in a spreadsheet, and they are yours to take further.

`pres2024_states.csv`

Your turn

None of these is answered above, and every one can be answered from the tables you just opened.

- `pres2024_states.csv` has `ev` and `margin` for every state. Sort by `margin` and add up the electoral votes of the closest states. How much of the map was actually in play?
- Work out electoral votes per voter for the largest and smallest states in the file. How much more is one person's vote worth in one place than another?
- The `other` column is zero in many rows. Check whether that is really true. What would a zero mean if it were not?
- Add up the `ev` column. Then find the smallest combination of states that reaches a majority, and see how few voters that represents.

REBUILD THIS DATA YOURSELF, WITH AN AI ASSISTANT

I want to rebuild a public dataset from its original source, without any starting files. Please do the following and show your work.

THE SOURCE. Jason Timm's `PresElectionResults` collection on GitHub, the state-level presidential returns file:

https://github.com/jaytimm/PresElectionResults/raw/master/data/pres_by_state.rda

No account or key is needed. It is an `.rda` file – R's own data format – so read it in R, or with a library that can open R data files. One row is one state in one election year; keep 2024. The compilation is assembled from public election records; it is somebody's careful stapling of fifty-one official sources, not an

official file itself, because no official national file exists.

One thing the source does not carry: electoral votes. Those are a fact about the 2020 census apportionment, not about the returns, so transcribe them yourself – fifty-one small numbers – and prove the transcription by checking the sum.

WHAT TO BUILD.

1. One row per state plus the District of Columbia: the Harris, Trump, and other vote shares, the winner, the margin, and the state's electoral votes.

CHECK YOUR WORK. The copy this book used was fetched in August 2026.

If your rebuild matches it, you should find:

- 51 rows, and electoral votes that sum to exactly 538
- Trump carries 31 of the 51, Harris 20
- the two biggest prizes are California at 54 and Texas at 40

The 2024 returns are settled history and should not move; the collection itself grows by one election every four years.
